Drilled Shafts Above the Mudline

Concrete Integrity Testing

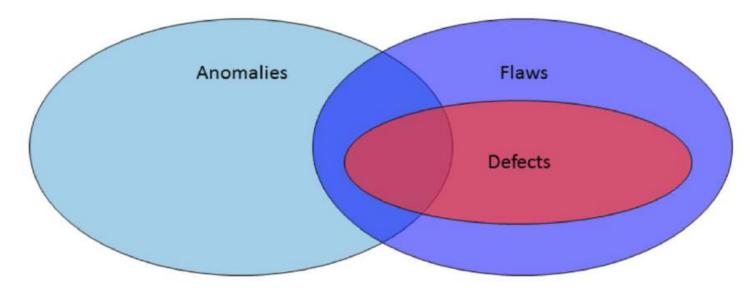

- Most common integrity methods:
 - Crosshole Sonic Logging (CSL), ASTM D6760
 - Thermal Integrity Profiling (TIP), ASTM D7949
- Bridge projects typically require one or both methods
- Each method has limitations
- Each methods requires semi-subjective interpretation of results
- Coring is typically the next investigative step when CSL or TIP raise concerns
- Coring has its own limitations

Terminology (DFI 2018)

Anomaly – Abnormal data that deviates from expectations, and may indicate a flaw or defect.

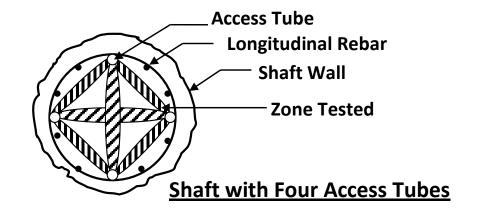

Flaw – Any imperfection in the planned shape or material of the foundation that may not necessarily affect its performance.

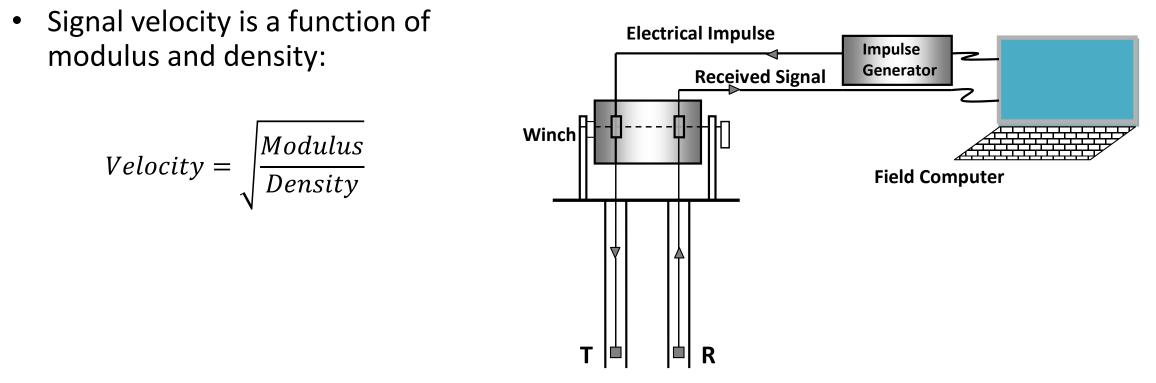

Defect – Any flaw that, because of size, location and inferred concrete properties, will have a significant adverse effect on the performance of the foundation.

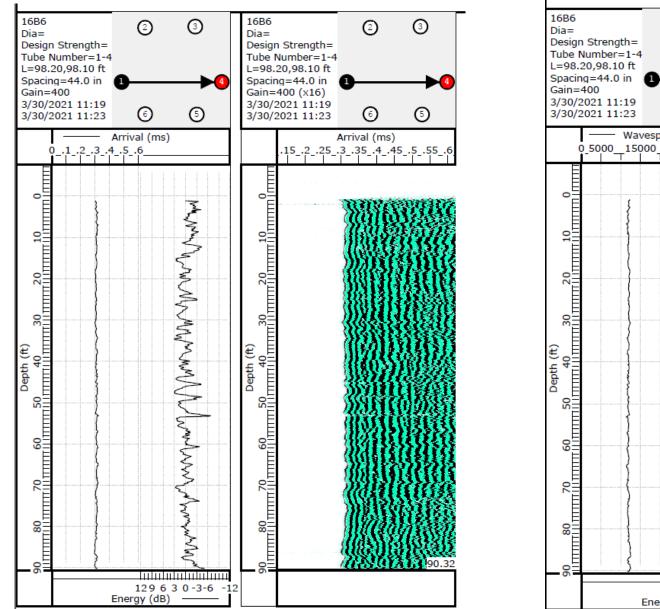

CSL

 Measure the travel time of acoustic signal pulses between tubes (Transmitter and Receiver)

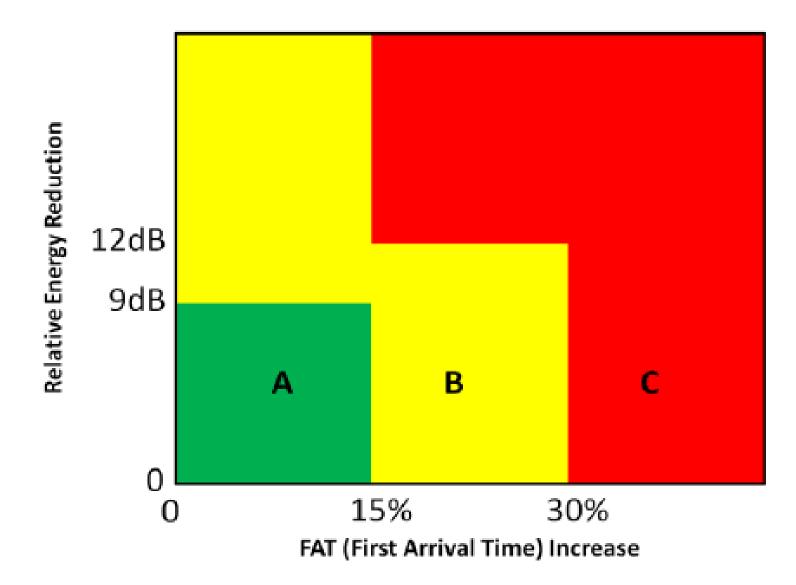

Typical CSL Software Output

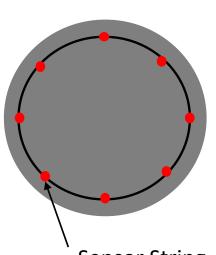

CSL Concrete Rating Criteria (DFI 2018)

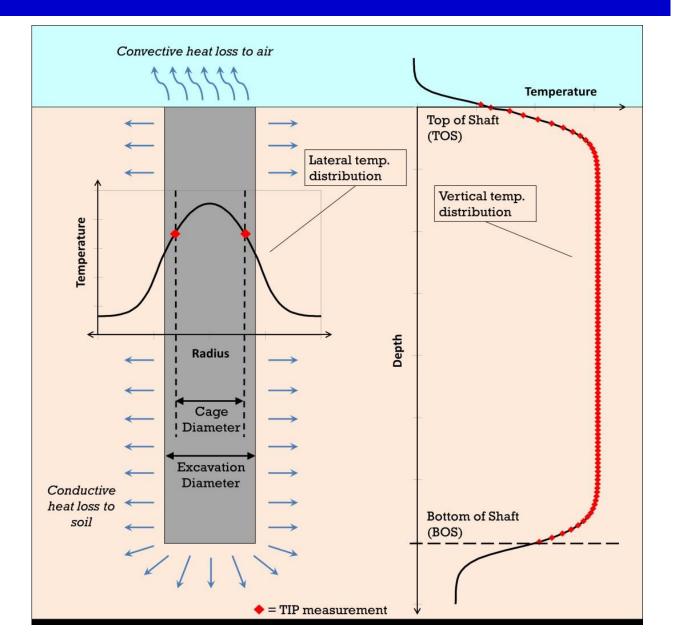

TIP

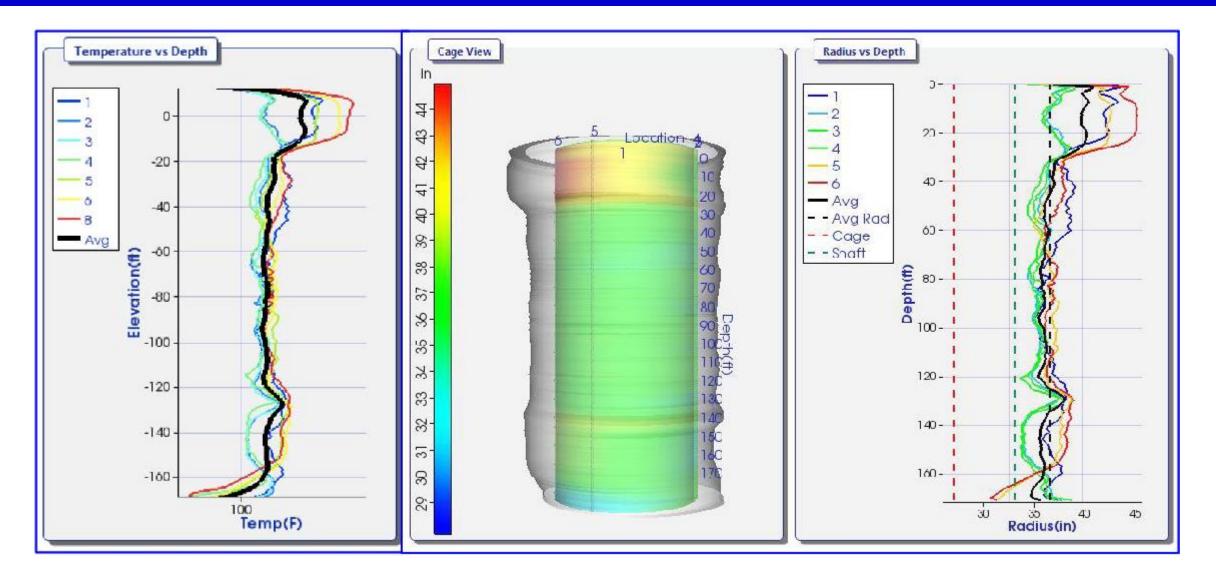

- Sensor String
- Measure concrete temperatures during curing with TIP wires tied to the cage (or probe method)
- Data must be collected during hydration period

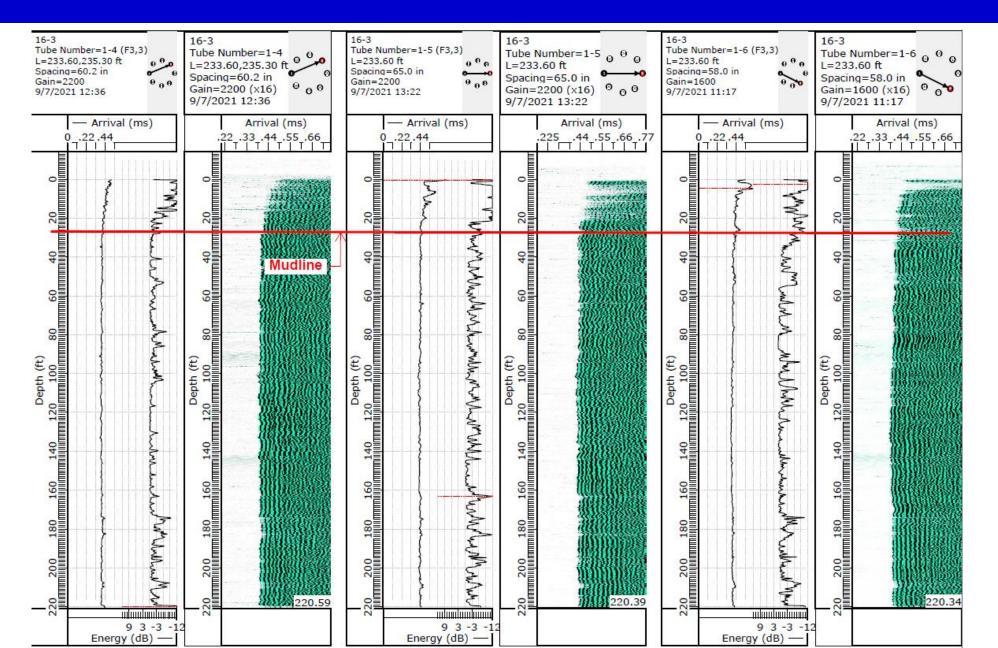

Typical TIP Software Output

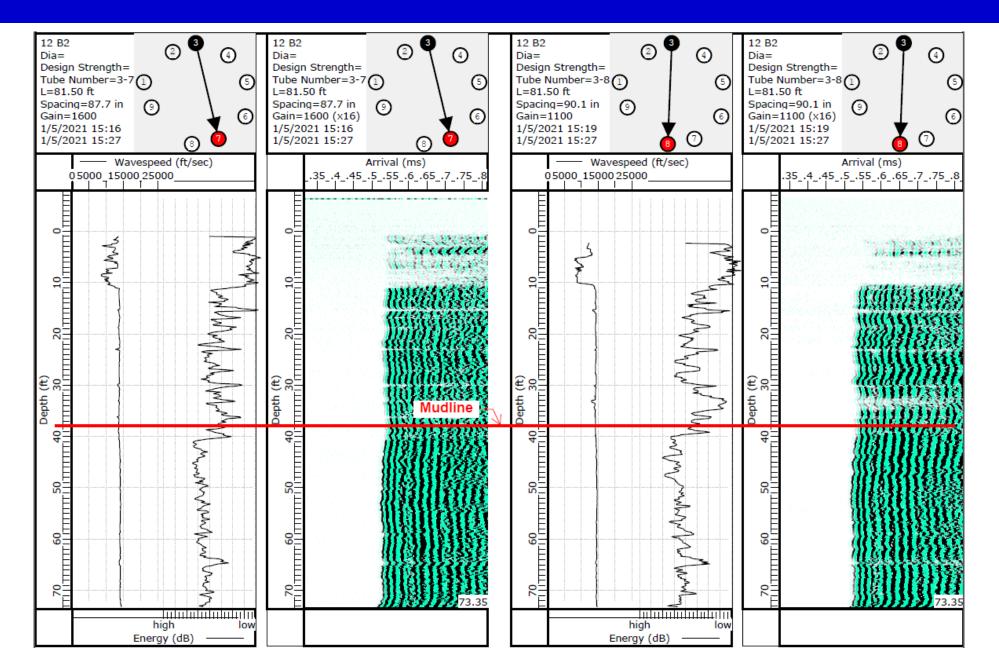

(From Martinello 2017)

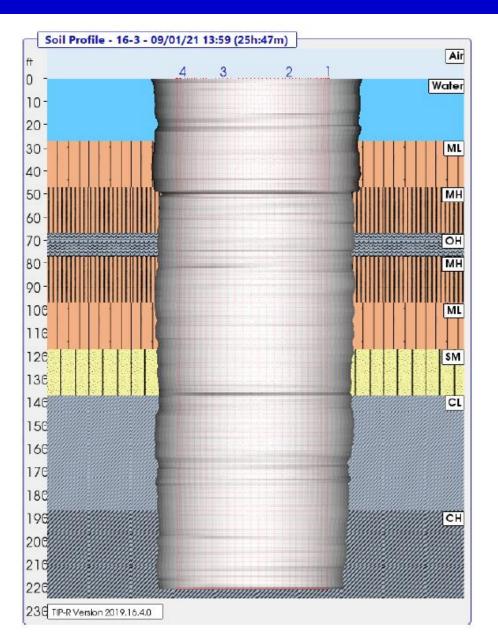

CSL Example: 8.5-ft Shaft in 27 ft of Water

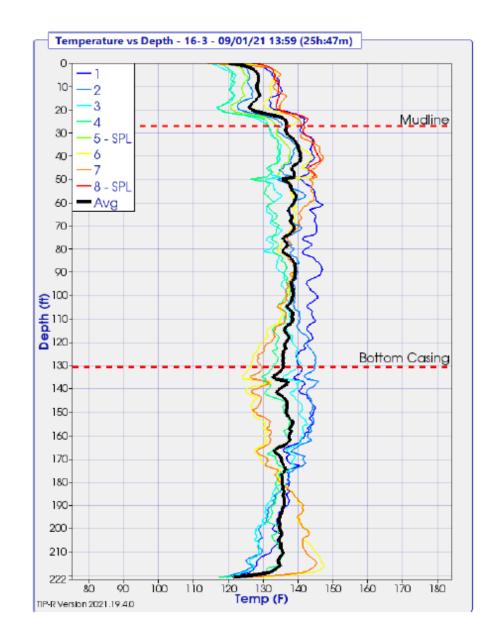

CSL Example: 10-ft Shaft in 38 ft of Water

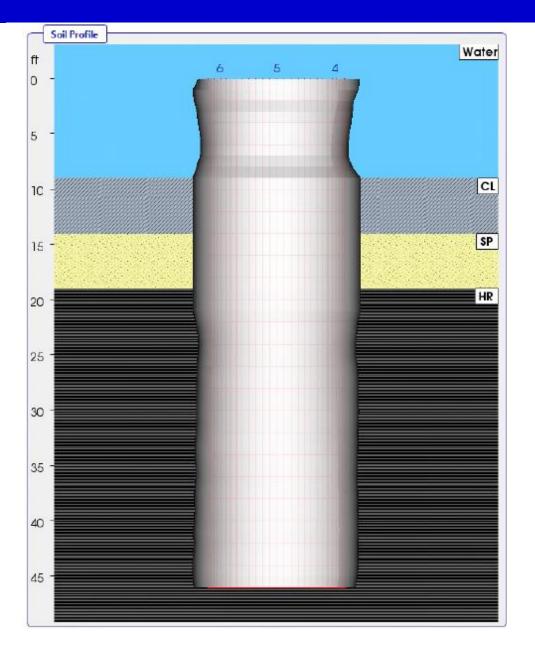

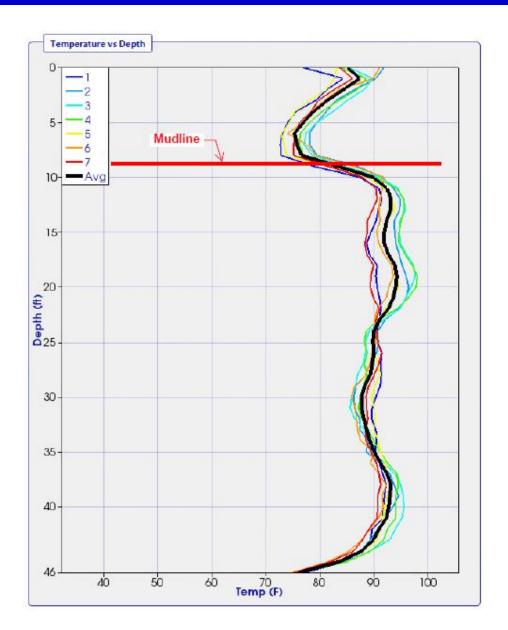

TIP Example: 8.5-ft Shaft in 27 ft of Water

TIP Example: 6-ft Shaft in 8 ft of Water

The Cause?

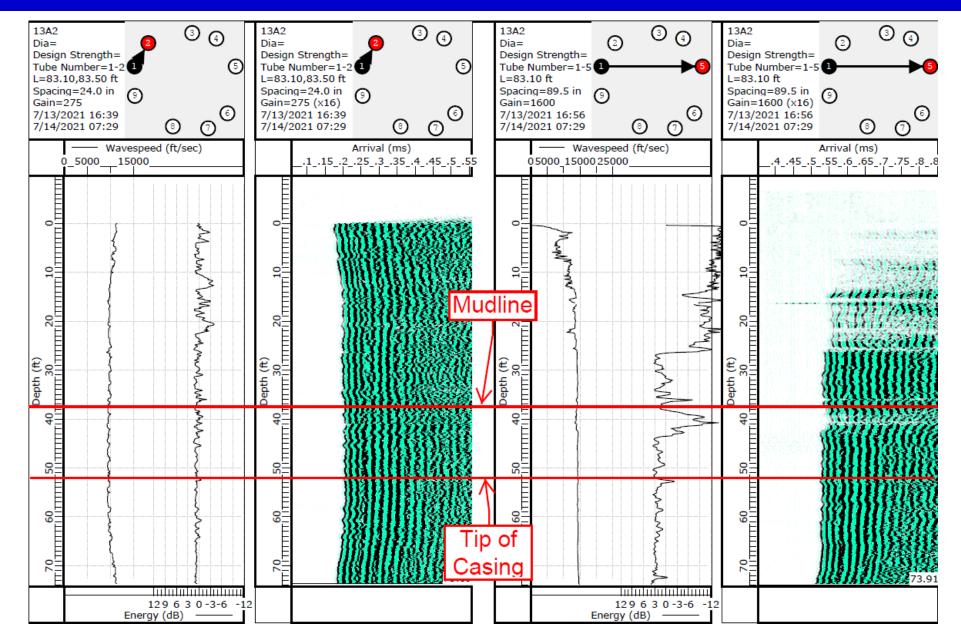

- Thermal conditions above the mudline are significantly different
 Flowing water
 - Surface water is often colder than groundwater
- Thermal conditions have a direct effect on TIP measurements
- Thermal conditions have an indirect effect on CSL measurements
 - Tube debonding
 - Rate of concrete curing
 - Concrete bleeding
- Mix design

Case Study 1: South Central U.S. River Crossing

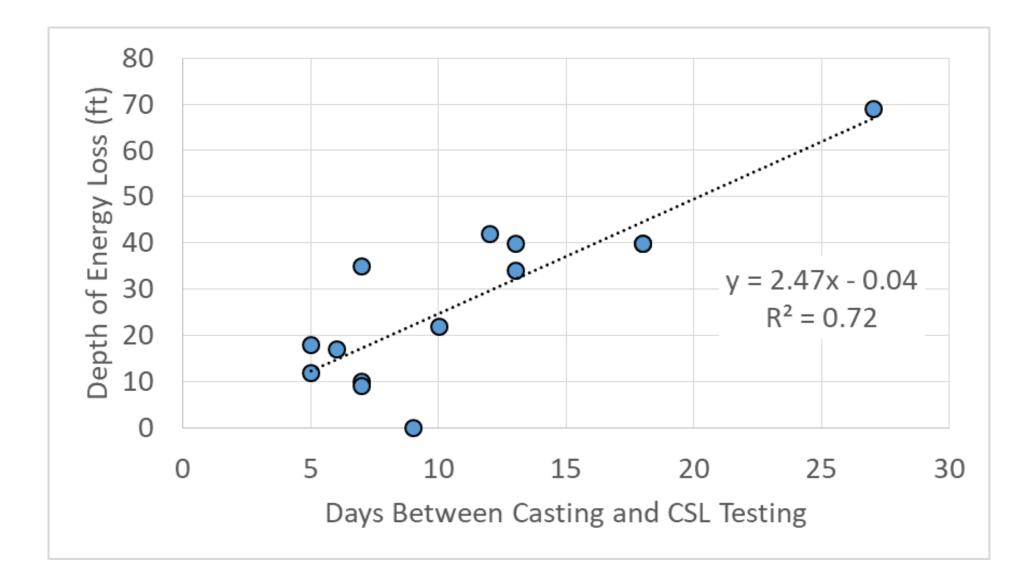

- 10-ft diameter shafts, permanently cased to rock
- CSL, no TIP
- Conventional tremie concrete mix (8-inch slump)
- Variety of ambient temperature conditions including some very hot
- Consistent CSL issues above the mudline with river shafts (17 of 18)
- Concrete bleed observed at some shafts
- No similar anomalies with land-based shafts of the same diameter, depth, and concrete mix
- Cored two shafts with bleed water channels encountered in one of the shafts
- Compressive strengths of core samples were above design strength

CSL Anomaly Signature

- Anomalies are significantly more pronounced in crossshaft shots than perimeter shots
- Anomalies primarily consist of signal energy loss
- Longer time between concrete placement and CSL testing usually exacerbates the issue

Depth of CSL Anomalies as a Function of Time

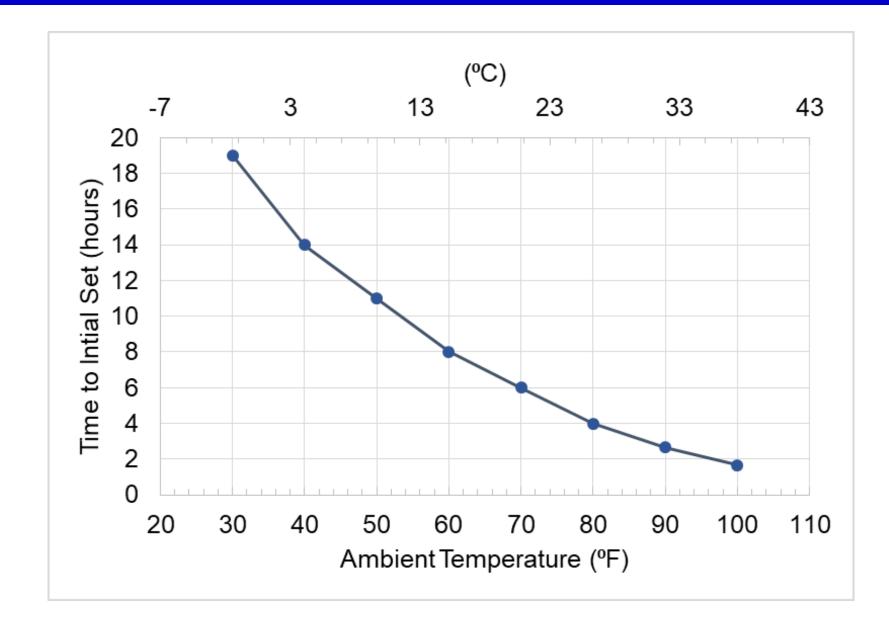

Bleed Water Channels

Time to Initial Set versus Ambient Temperature

Case Study 2: Raritan River New Jersey

- 8-ft diameter shafts, permanently cased
- CSL
- TIP performed on one shaft in addition to CSL
- High-flow, self-consolidating concrete mix
- Variety of ambient temperature conditions including some very cold
- Concrete bleed observed at some shafts
- Consistent CSL issues above the mudline with all river shafts (86 shafts)
- Cored six shafts with some bleed water channels encountered
- Compressive strengths of core samples were above design strength

CSL Anomaly Signature

- Anomalies are significantly more pronounced in crossshaft shots than perimeter shots
- Anomalies primarily consist of signal energy loss

Bleed Water Channels

Comparison of TIP and CSL

Summary and Closing Remarks

- Different thermal conditions above the mudline can influence TIP and CSL results.
- Influence on CSL results is possibly attributed to tube debonding and/or concrete bleed.
- TIP interpretation is difficult in the zone above the mudline, especially when CSL results show anomalies in the same zone.
- The examples presented are not defective shafts, but rather shafts with anomalous data due to the thermal conditions.
- Evaluation of CSL and TIP results must be considered in the context of what is known about the concrete placement.
